

# Partial Hiding in Public-Key Cryptography

Eabhnat Ní Fhloinn\* and Michael Purser

School of Mathematics, Trinity College Dublin, Ireland.

**Abstract.** This paper explores the idea of exposing sections of the private key in public-key cryptosystems whose security is based on the intractability of factorising large integers, such as RSA. While substantial work has been done in the area of partial key exposure, the aim has been to investigate the implications of *inadvertant* partial exposure of the private key. We focus instead on the potential advantages of *deliberately* revealing portions of the private key, and so, term our scheme “partial hiding”. Significant segments of the key are made publicly available, greatly reducing the amount of data which must be securely hidden. This allows us to use biometric readings to protect the *secret* portion of the private key. We use iris recognition with error-correcting codes for this purpose. We propose an implementation of this system for RSA, and consider the potential risks and advantages of such a scheme.

**Keywords:** Public-key cryptography, Partial key exposure, Partial hiding, RSA, Iris, Biometrics

## 1 Introduction

In public-key systems which rely on the intractability of factorising large numbers, it is generally recommended that private keys be of length *at least* 1024 bits. These private keys are securely stored and hidden from public access. In this paper, we address the question of whether all these bits need to be secret, or if it would be sufficient to store a portion securely and leave the remainder publicly available. Our motivation in doing so is to allow us to use biometrics directly to protect private keys, as will be explained below.

Although there has been substantial work done to date in the area of partial key exposure, it would appear that the aim of this work has been to investigate the implications of inadvertant exposure of some part of the private key. We term our scheme *partial hiding*, focusing instead on the potential advantages of deliberately revealing portions of the private key.

While partial hiding may be advantageous in schemes which rely on the intractability of factorising large integers for their security, the same cannot be said for discrete-log based systems. This is because most of these schemes require that the private key is a random number of length 160 bits. Firstly, this is not overly large and secondly, it needs to be of this length in order to frustrate brute-force attacks on the key. Thus, shortening it in any way would seem to leave it vulnerable to this most basic of attacks. Ultimately, even if partial hiding was

---

\* evoflynn@maths.tcd.ie

possible with such systems, the savings in storage space would be negligible and therefore we will not consider such schemes any further.

### 1.1 Partial Hiding

In mathematical notation, the idea of partial hiding could be expressed by letting  $P$  be the private key of length  $p$ ,  $S$  be the bits not hidden and  $X$  be the bits hidden. Using the exclusive-OR operation (represented by  $\oplus$ ) to combine these, we have

$$P = S' \oplus X' , \quad (1)$$

where  $S'$  and  $X'$  represent bit-strings of length  $p$ , consisting partly of  $S$  or  $X$  respectively and padded with zeros in positions where bits were extracted. For example, if  $P$  were 10 bits long, and  $X$  consisted of the four “middle” bits, then we would have

$$P = S_1 0000 S_2 \oplus 000 X 000 . \quad (2)$$

It is vital that  $X$  is sufficiently large to render a brute force attack impractical; if an attacker has access to the public key, the algorithm and  $S$ , he should not be able to determine the private key  $P$  by trying all possible values of  $X$ .

There are several ways in which the bits of  $X$  could be extracted from  $P$ : we could remove the least significant bits (LSBs); the most significant bits (MSBs); or a random scattering of bits from throughout the key. Randomly selected bits would seem initially to give a greater level of security. However, if the bits are randomly selected according to some secret rule, then we need to also store their original position in the key in order to recover them later on. Storing these positions, as well as the values of the bits, within the  $n$  bits allowance we choose for  $X$  reduces the overall number of bits of the private key that can be hidden thus - meaning that we could only store  $n/2$  bits of the key and  $n/2$  positions, instead of  $n$  bits of the private key, which is a clear disadvantage.

There are several issues which need to be addressed in the proposed idea of partial key hiding. The most important of these is how many bits it is safe to expose, and exactly which bits these might be. However, it is also vital that the “secret” portion of the private key be securely stored in such a way that an attacker cannot gain access to it. We suggest the use of iris recognition with error-correcting codes to overcome this problem.

### 1.2 Biometrics

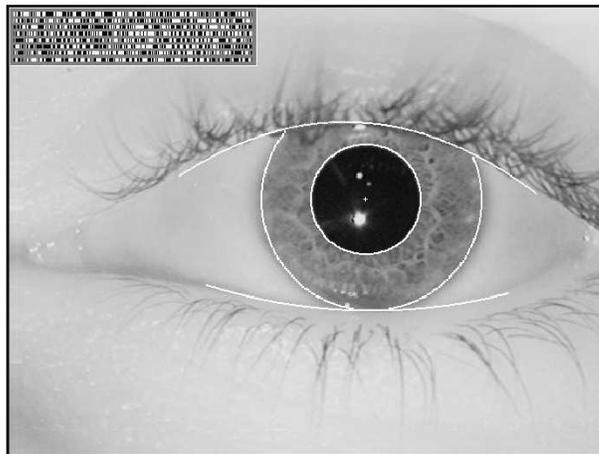

A biometric measures an individual’s unique physical or behavioural characteristics for recognition or authentication purposes. Currently, physical rather than behavioural characteristics are more commonly used for biometric identification. Biometric identification is made up of two stages: *enrolment* and *verification* [16]. Enrolment refers to the process of obtaining several readings of the biometric in question from a new user and extracting notable features to store in a template for comparison purposes later on. Verification consists of acquiring a new reading

from the user and comparing the result with the previously-stored template in order to accept or reject the user.

Although we originally considered working with fingerprints, which are perhaps the most widely accepted biometric in use today, we concluded that iris templates were better suited to our purposes. Unlike fingerprints, the iris benefits from a high level of natural protection in the body [5], being unaffected by dirt, weather conditions, sweat and various other external influences which can adversely affect a fingerprint reading. Although it is an internal organ, it is externally visible, allowing for unintrusive imaging from a distance. It also contains an intrinsic polar geometry leading to an ease of applying a natural coordinate system that is lacking in other biometrics [4]. An in-depth report was produced by the U.K. National Physical Laboratory in 2001 [12], following a detailed study of the performance and reliability of various biometrics. In 2.73 million cross-comparisons, there were no false matches reported for the iris recognition technology. This impressive reliability demonstrates that the iris is probably the most suitable biometric for use in public-key systems.

## 2 Related Work

The algorithm currently in use for almost all iris recognition systems was developed by John Daugman [4]. An image of the user’s eye is obtained and the iris

**Fig. 1.** Example of an iris image segmented using Daugman’s algorithm, with the IrisCode (bit stream) visible in the top left corner. The image has been taken monochromatically with near-infrared illumination in the 700-900nm band at a distance of approximately 35cm. [4]

is segmented from the overall image, as illustrated in Fig. 1. An “IrisCode” is

then calculated based on a phase sequence description of the iris. This IrisCode is 256 bytes in length and is accompanied by a further 256 “masking” bytes which provide information as to which bits of the image have been corrupted and should be ignored. In order to perform iris recognition, the IrisCodes from two irises are compared using a test of statistical independence. If two different irises are used, this test will be passed - if two IrisCodes computed from the same iris are compared, the test will be failed. Thus, in order to successfully identify an individual, this statistical test needs to be *failed*.

The use of error-correcting codes to correct iris readings and compare them with previously stored templates was suggested by Davida, Frankel and Matt [6]. This scheme increases security by storing the template’s check digits along with a hash of the template, but currently their implementation appears to lack sufficient error-tolerance. We have proposed an enhanced version of this scheme, which relies on Reed-Solomon codes over  $\text{GF}(2^8)$  [11]. This scheme introduces erasures as well as errors, greatly increasing the error-correcting capacity. For partial hiding, we use a modified iris recognition system, which uses Daugman’s algorithm to produce the IrisCode, but relies on our modification of Davida et al’s error-correction scheme to match the iris templates. Let  $x$  represent an iris reading and  $y$  the secret portion of the private key. To enrol a new user, we have

$$x \oplus y = z \text{ ,} \tag{3}$$

where  $\oplus$  represents exclusive-OR. A file is created for the user, storing  $z$  along with the check digits corresponding to  $x$ . In order to recreate  $y$ , the user submits to another iris reading,  $x'$ , which we correct back to  $x$  using the check digits stored in the user’s file. Having retrieved  $z$  from the file, we then calculate

$$x \oplus z = y \text{ ,} \tag{4}$$

and have thus restored the secret portion of the private key.

In terms of partial key exposure, Boneh, Durfee and Frankel [2] explored several different attacks on RSA [14] following partial exposure of the private key. Interestingly, for low-exponent RSA, they showed that the most significant half of the bits of the private key  $d$  are automatically “leaked” and that this has no adverse effect on security. Their results for low-exponent RSA also show that only a quarter of the LSBs of  $d$  are sufficient for an attacker to obtain all of  $d$ .

However, Steinfeld and Zheng [17] went on to show that this result only holds if no more than the least significant bit of  $p$  and  $q$  is equal, where  $p$  and  $q$  are primes such that the modulus  $N = pq$ . This led them to propose a system for low-exponent RSA in which the  $m$  LSBs of  $p$  and  $q$  are identical. In this case, they prove that, if the system is secure with no bits exposed, it is secure if up to  $2m$  LSBs of  $d$  are exposed. They go on to suggest that this result may be used to some advantage to reduce the “computational bottleneck” of the decryption operation in RSA.

Hinek, Low and Teske [7] investigate multi-prime RSA (i.e. 3 primes or more) in relation to partial exposure of the private key. They claim that the BDF

attack is completely ineffective for 3-prime RSA as the number of solutions is exponential in the bit-size of the RSA modulus.

Most recently, Blömer and May presented a paper entitled “New Partial Key Exposure Attacks on RSA” [1], in which they produce even stronger results for RSA than those suggested by BDF. In addition, they also produce attacks on partial key exposure in the Chinese Remainder Theorem (CRT) version of RSA [13], suggesting that for low-exponent RSA, half the bits of  $d_p = d \bmod (p - 1)$  are sufficient to factorize the modulus  $N$ .

### 3 Partial Hiding in RSA

The latest recommendations [9] for RSA estimate that moduli of minimum size  $n = 1024$  bits are safe until at least 2010 against the most powerful known factoring algorithms. However, a larger key-size, such as  $n = 2048$ , is already more appropriate for many applications. Thus, we let  $N = pq$  be an RSA modulus of size  $n = \log_2 N = 2048$  bits, with  $p$  and  $q$  each 1024 bits long. We wish to choose a “small” exponent  $e$ , but common values previously used, such as  $e = 3$  or  $e = 17$ , are no longer considered safe [10]. Thus, we let  $e = 2^{16} + 1 = 65537$ . From [2, pp 6], we know that the most significant 1024 bits of the private key,  $d$ , are automatically “leaked” in low-exponent RSA such as this, but this does not affect the security of the system.

We base our system on an adaptation of that proposed by Steinfeld and Zheng [17], setting the  $m$  least significant bits (LSBs) of  $p$  and  $q$  to be equal. They claim that if low-exponent RSA in this form is secure with  $no$  bits exposed, then it is secure if up to  $2m$  LSBs are exposed. Thus, if we let

$$m = \frac{n}{4} (1 - \epsilon) \quad , \quad (5)$$

with small  $\epsilon$  in a secure system, we can expose the  $n/2$  ( $=1024$ ) MSBs of  $d$  and the  $(n/2)(1 - \epsilon)$  ( $= 1024 - 1024\epsilon$ ) LSBs of  $d$  and still have a secure system.

We must now determine the optimum value for  $\epsilon$ . We want  $\epsilon < 0.5$ , as there is a considerable reduction in the cost of computation if this is true [17]. However, we also need to ensure that  $2^y$  is too large to exhaustively search for  $y$  unknown bits of  $p$  or  $q$ , where  $y = (\epsilon n/4)$ .

Based on Silverman’s estimates [15] on the costs of breaking cryptographic keys, with a budget of \$10 million dollars,  $2^{56}$  takes  $< 5$  minutes to crack;  $2^{80}$  takes 600 months;  $2^{96}$  takes 3 million years;  $2^{128}$  takes  $10^{16}$  years. Using Table 1, we reject values as low as  $\epsilon = 0.125$ , as  $2^{64}$  is too low for security. The current standards for symmetric cryptography suggest to use 128 bits for AES, so a value of  $\epsilon = 0.25$  would provide comparable security. With this choice, we have  $m = 384$  and a value of  $2^{128}$ , which would seem to suit our purposes well while still being sufficiently large to be considered safe.

Thus, the 384 LSBs of  $p$  and  $q$  will be equal. In order to generate these primes, simply find  $p$  in the usual fashion, fix the 384 LSBs of  $q$  to be identical to  $p$ , and produce a prime  $q$  of this form [18]. This is expected to be as efficient as

**Table 1.** Possible values for  $\epsilon$ 

Size of $N$	Size of $p$ (or $q$ )	Value of $\epsilon$	Value of $m$	Value of $2^y$
2048	1024	0.5	256	$2^{256}$
2048	1024	0.25	384	$2^{128}$
2048	1024	0.125	448	$2^{64}$

the standard independent primes generation algorithm for random RSA moduli, where each candidate for  $q$  is chosen independently of  $p$  as a random odd integer.

If we let  $\epsilon = 0.25$ , then the 1024 MSBs and the 768 LSBs of  $d$  can be exposed for low-exponent RSA, and if the original system was secure, then this new system should also be. This means we need to keep 256 bits securely hidden at all times, in bit positions from 769 to 1024 inclusive, assuming an offset of 1 and working from right to left.

#### 4 CRT RSA Partial Hiding

While considering improvements of the RSA system, it is natural to attempt to implement these using the Quisquater-Couvreur [13] version of RSA, which uses the Chinese Remainder Theorem (CRT) to speed up calculations in the scheme. In this approach, two separate quantities

$$\begin{aligned} d_p &= d \bmod (p - 1) , \\ d_q &= d \bmod (q - 1) \end{aligned} \tag{6}$$

are used to encrypt and decrypt each message. This means that if we have either  $p$  or  $q$ , we should be able to recreate all the remaining information needed from our public information. Thus, while we need to retain the values of  $p$  and  $q$ , we cannot make these publicly known in their entirety. Therefore, both of these values need to be at least partially hidden.

There are two main approaches to partial hiding to be considered:

1. Partially store  $p$  and  $q$ . Partially store  $d_p$  and  $d_q$ . Restore these hidden portions to the “known” public portions of  $d_p$  and  $d_q$  each time.
2. Partially store  $p$  and  $q$ . Partially store  $d$ . Generate  $d_p = d \bmod (p - 1)$  and  $d_q = d \bmod (q - 1)$  each time, using both partially stored and publicly known information.

If we consider option 1, certain restrictions must be imposed immediately; less than 50% of the LSBs (or MSBs) of  $d_p$  or  $d_q$  can be made public, as there is an attack on low public exponent CRT RSA [1] if more than this amount is exposed.

If we deal with an RSA modulus of size  $n = 2048$ , then  $p$  and  $q$  are of length 1024 bits and  $d_p$  and  $d_q$  are approximately this size also. The 384 LSBs of  $p$  and  $q$  are identical in our system; the 640 MSBs are not. However, Coppersmith [3]

describes a method of factoring  $N$  given the MS half of the bits of  $p$ . Thus, it would appear to make sense to securely hide the 640 MSBs of  $p$  and  $q$  using the iris template. We must also store over half of the bits of  $d_p$  and  $d_q$ , which means that, in total, we would need to store over 2304 bits of data in this scheme. If we wish to use iris templates to encrypt this data, we encounter problems at this point, as an iris template consists of only 2048 bits of data, and so a direct XOR with the RSA information is not possible. Thus, we can only continue with this particular approach if we reduce the size of our modulus and deal with 1024-bit RSA in place of 2048-bit RSA, or possibly consider other biometrics.

If we turn our attention now to the second approach, we again choose to partially hide the 640 MSBs of both  $p$  and  $q$ . As suggested above for RSA, we store only the 256 “middle” bits of  $d$ , which gives us a total of 1536 bits to be stored, which could easily be hidden by XORing with an iris template.

We must now consider whether we have introduced additional vulnerability to the system by partially revealing  $p$  and  $q$ , and if so, to what extent this affects the overall system. As before, bits 1-768 and 1025-2048 of  $d$  are made public, with only bits 769-1024 securely hidden. We are proposing to reveal bits 1-384 of  $p$  (and  $q$ ). If it is possible to determine either the least significant half or the most significant half of the bits of  $d_p$  as a result, then our system is not secure.

$p$  is prime, so the least significant bit of  $p$  will always equal 1. Thus, to obtain  $(p - 1)$ , we must simply change this least significant bit to 0. Let  $p'$  be the 384 LSBs of  $p$  that are publicly available. We now show in a general way that there is no clear link between the LSBs of a random number,  $x$ , calculated  $\text{mod}(p - 1)$  and  $\text{mod}(p' - 1)$ . This ensures that the LSBs of  $d_p$  could not be directly calculated from the partial knowledge of  $p$  and  $d$  that we have exposed.

Let

$$p = t(2^{384}) + p' , \quad (7)$$

where  $p$  and  $t$  are not publicly known. Clearly, this means that

$$p - 1 = t(2^{384}) + p' - 1 . \quad (8)$$

If we now choose a random value  $x$ , larger than  $(p - 1)$ , we can calculate  $x \text{ mod } (p - 1)$  and  $x \text{ mod } (p' - 1)$  and observe if there are any similarities in the LSBs. Now let

$$a = x \text{ mod } (p - 1) = x - k(p - 1) \quad (9)$$

$$b = x \text{ mod } (p' - 1) = x - k'(p' - 1) , \quad (10)$$

for some  $k, k'$ . Thus,

$$a - b = (k' - k)(p' - 1) - kt(2^{384}) . \quad (11)$$

Clearly,  $kt(2^{384})$  only affects the MSBs. The LSBs are controlled by  $(k' - k)(p' - 1)$ . As we know  $p'$ , we also know  $k'$ , but  $k$  is unknown and unguessable provided  $x$  is significantly larger than  $(p - 1)$ . Thus, the LSBs of  $a$  and  $b$  differ by the product of  $(p' - 1)$  and a pseudo-random integer  $(k' - k)$ . Provided that this is large enough, it cannot be guessed or found by some brute force approach.

These calculations are done knowing the entire value of  $x$ , but in CRT RSA, an attacker would have only a portion of  $d$ , making these calculations even more uncertain. Thus, the LSBs of  $d_p$  cannot be directly calculated in this fashion.

## 5 Attacks on Partial Exposure

The most basic attack on partial hiding in RSA consists simply of a brute force approach, where an attacker tries all possible combinations for the hidden portion of the private key,  $d$ . We are proposing to hide bits 769-1024 of a 2048-bit  $d$ . This means that only 256 bits must be uncovered to break the system. However, an attacker would need to calculate the values of all 256 of these bits before being in a position to judge if any were correct. We believe that the parameters we have chosen for this system are secure under current computing power.

Our scheme is not vulnerable to any of the attacks mentioned in [2], as it is based on the Steinfeld-Zheng system, which is resistant to these attacks. However, Blömer and May [1] produced a paper recently which contains several attacks which may be applicable to such a scheme, depending on the parameters used. We will now look at each of the relevant attacks in detail and discuss whether they might pose a threat to the system we have proposed.

### 5.1 Blömer-May Attack 1

We begin with the “strongest” attack, which works for all  $e < N^{\frac{7}{8}}$ . In order for this attack to work, a certain portion of the LSBs of  $d$  must be exposed. Blömer and May work with a modulus  $N$  of bit-size  $n = 1000$  and use varying bit-sizes of 300, 400 and 500 bits for  $e$ . This means that a minimum of 725, 782 and 834 LSBs of  $d$  respectively are needed in order for the attack to work. These values are calculated from the following theorem, proven in their paper:

**Theorem 5.1 (Blömer-May).** *For every  $\epsilon > 0$ , there exists  $N_0$  such that for every  $N \geq N_0$ , the following holds:*

*Let  $(N, e)$  be an RSA public key with  $\alpha = \log_N(e) \leq \frac{7}{8}$ . Let  $d$  be the private key. Given  $d_0, M$  satisfying  $d = d_0 \bmod M$  with*

$$M \geq N^{\frac{1}{6} + \frac{1}{3}\sqrt{1+6\alpha+\epsilon}}, \quad (12)$$

*then  $N$  can be factored in polynomial time.*

If we apply this theorem to our proposed system, we can determine whether there is a threat posed to our scheme by this attack. Our modulus  $N$  is of size  $n = 2048$  bits. We have set  $e = 2^{16} + 1 = 65537$ . We expose the 768 LSBs of  $d$  and must now calculate what is the minimum number of LSBs required in order for the attack to proceed.

If  $N$  is of length 2048 bits, the smallest such number is  $2^{2047}$ . From the theorem, if  $M$  is sufficiently large (where  $M$  denotes the number of LSBs known), then our system can be broken. In order to obtain the minimum number of LSBs

needed, set  $\epsilon \approx 0$  and neglect this term completely. We need to calculate the value of  $\alpha = \log_N(e)$ .

$$\begin{aligned}\alpha &= \log_{2^{2047}}(65537) \\ &= 0.0078163273 \ .\end{aligned}\tag{13}$$

We can now determine  $M$  using (12):

$$\begin{aligned}M &= (2^{2047})^{\frac{1}{6} + \frac{1}{3}\sqrt{1+6\alpha}} \\ &= 2^{1039.3167} \ .\end{aligned}\tag{14}$$

Thus, a minimum of 1040 LSBs would be needed for this attack to work, and as we only expose 768 LSBs, our system would seem to be secure against this approach.

## 5.2 Blömer-May Attack 2

The next attack described by Blömer and May to which our scheme may be vulnerable involves a provable attack for almost all  $e < N^{\frac{1}{2}}$ . Here, a vulnerability is introduced if

$$N^{\alpha + \frac{1}{2} + \epsilon} \leq M \leq 2N^{\alpha + \frac{1}{2} + \epsilon} \ ,\tag{15}$$

where  $0 < \alpha, \epsilon < 1/2$  and  $M$  represents the known LSBs again. If this is not the case, then the attack will not work. Calculating as before for our system, taking  $\alpha, \epsilon \approx 0$  for the smallest number of bits acceptable, we get

$$N^{\frac{1}{2}} \leq M \leq 2N^{\frac{1}{2}} \ .\tag{16}$$

This in turn gives us

$$2^{1023.5} \leq M \leq 2^{1024.5}\tag{17}$$

so  $M = 2^{1024}$ . Thus, the 1025 LSBs of  $d$  would need to be exposed to make our system vulnerable to this attack, whereas we only expose the 768 LSBs of  $d$ .

## 5.3 Blömer-May Attack 3

The final Blömer and May attack which may introduce a vulnerability to our scheme is based on CRT RSA. The attack enables an adversary to recreate  $d$  given the least significant half of the bits of  $d_p$  and works for low-exponent RSA such as  $e = 2^{16} + 1$ . In our system, the least significant half of the bits of  $d_p$  is only of length 512 bits. We expose the 768 LSBs of  $d$ , but in order to determine the value of  $d_p$ , it is necessary to know  $p$ . Although an attacker knows that the 384 LSBs of  $p$  and  $q$  are equal, and has access to the value of  $N = pq$ , these values are too large for him to successfully decipher  $p$  from this knowledge. The correctness of each bit that would be guessed would depend on the correctness of the bit before it. Clearly, the LSB will always be revealed, but we believe that the value of any further bits is still protected. Thus, our system is secure against this form of attack.

#### 5.4 Wiener’s Continued Fractions Attack

Wiener’s attack [19] relies on continued fractions to find the value of  $d$ . It is successful for short secret exponents, which are up to one-quarter the size of the modulus,  $N$ . Our secret exponent is of length 2048 bits, but only 256 of these are securely hidden. We must investigate whether a continued fractions approach could expose a vulnerability in this scheme.

Let our secret exponent,  $d$ , consist of three sections in which  $d_0$  represents the known 1024 MSBs,  $d_1$  the unknown “middle” 256 bits and  $d_2$  the known 768 LSBs. Then we have

$$d = d_0 2^{1024} + d_1 2^{768} + d_2 . \quad (18)$$

This means we can adapt Wiener’s notation and write:

$$e (d_0 2^{1024} + d_1 2^{768} + d_2) = K \operatorname{lcm}(p - 1, q - 1) + 1 , \quad (19)$$

for some  $K$ . This gives us

$$e (d_0 2^{1024} + d_1 2^{768} + d_2) = \frac{k}{g} (p - 1) (q - 1) + 1 , \quad (20)$$

where  $G = \operatorname{gcd}(p - 1, q - 1)$ ,  $k = K / \operatorname{gcd}(K, G)$  and  $g = G / \operatorname{gcd}(K, G)$ . At this point, Wiener manipulates the formula to read:

$$\frac{e}{pq} = \frac{k}{dg} (1 - \delta) \text{ where } \delta = \frac{p + q - 1 - \frac{g}{k}}{pq} . \quad (21)$$

If  $d$  is small, it can now be found using continued fractions. However, in our case, an attacker would need to be able to extract  $d_1$  in (20) from the sum in order to be able to launch an attack in this fashion. If  $d$  could be expressed as a product in place of a sum, in which the unknown  $d_1$  was less than a quarter of the bits of  $N$ , then possibly an adaptation of Wiener’s attack could be used, but we do not believe this can be done.

## 6 Conclusion and Future Work

In this paper, we propose a implementation of RSA in which part of the private key is made publicly available, without allowing an attacker to uncover the remainder of the private key. We suggest the use of iris readings to securely encrypt the “secret” portion of the private key, in order to increase security. Two different implementations are described: one involving general RSA, the other using the Quisquater-Couvreur version. We also explore several possible attacks on these systems and show that they are resistant to all of these attacks.

Partially hiding the private key allows the decryption process to be completed more quickly in RSA, which may be advantageous in implementations such as smart cards. It also allows us to use a biometric such as an iris reading to encrypt the hidden portion, as there would be insufficient information in an iris reading to directly XOR it with an entire private key. This system could also be implemented using a different biometric, or combination of biometrics, an issue that we may explore further in the future. Thus, we believe there are numerous potential advantages to this application of partial hiding.
